

Course: Python language

Ali ZAINOUL

for Keyce Academy
May 14, 2023

- 1 Introduction to Python
 - Necessary tools
 - Installing Python
 - Python and it's ecosystem
 - Ecosystem
 - Most used libraries in Python
 - Python, qué saco ?!
 - First program in Python
 - Plan of the course
- 2 Basic Syntax, Variables, and Data Types
 - Basic Syntax in Python
 - Variables in Python
 - Data Types in Python
 - Data Structures in Python
 - Conditionnal Structures
- 3 Functions and Modules
 - Functions and Parameters

- Function in Python
- Lambda Functions
- Variable number of parameters in a function
- Functions with key/value parameters
- Generators
- Modules and Importing

4 Files I/O in Python

5 Exception Handling in Python

6 Fundamental Principles of OOP

Python ?!

■ Python in brief:

- Powerful programming language;
- Easy to use and learn;
- Open source;
- Dynamic typing language

■ Advantages of Python:

- Adapted to newbies;
- Used in a large scale and variety projects in industry;

Figure: Python logo

Necessary tools

- Integrated Development Environment (IDE)
Choice between: PyDev, Microsoft Visual Studio, Sublimetext ...

Figure: Best IDE

- Text Editor & compilation *via* terminal

Installing Python on Windows

- Download the latest Python installer from the official website.
- Open Command Prompt and navigate to the folder where the installer was downloaded.
- Run the installer by typing the following command: `python installer-file-name.exe`
- Follow the instructions on the screen to complete the installation.
- To verify that Python was installed correctly, open Command Prompt and type `python` to launch the Python interpreter.

Installing Python on Linux

- Open the terminal and type the following command: `sudo apt-get install python3`
- Enter your password when prompted.
- Wait for the installation to complete.
- To verify that Python was installed correctly, type `python3` in the terminal to launch the Python interpreter.

Installing Python on MacOS

- Open the terminal and type the following command: `xcode-select --install`
- Follow the instructions on the screen to install Xcode Command Line Tools.
- Once Xcode Command Line Tools is installed, type the following command in the terminal: `brew install python3`
- Wait for the installation to complete.
- To verify that Python was installed correctly, type `python3` in the terminal to launch the Python interpreter.

Ecosystem

Figure: Ecosystem Python

Most used libraries in Python

- Pandas: much used in data science. (CSV, TXT, SQL)
- Numpy: numerical analysis and calculus, mathematical functions, objects and operations, linear algebra.
- Matplotlib: library used in order to trace and visualize data with graphs.

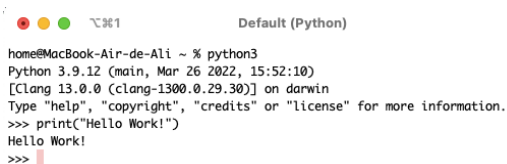

Python, quésaco ?!

Python is a programming language that is:

- Interpreted;
- Multiparadigm et multiplatforms;
- which promotes the:
 - *structured imperative programming*
 - *functionnal programming*
 - *Object Oriented Programming*

First program in Python

```
print("Hello Work!")
```

A screenshot of a macOS terminal window. The title bar shows three colored window control buttons (red, yellow, green) and the text "Terminal". The terminal content shows the command "python3" being executed, followed by the Python version and system information. The user then enters a print statement, and the output "Hello Work!" is displayed.

```
home@MacBook-Air-de-Ali ~ % python3
Python 3.9.12 (main, Mar 26 2022, 15:52:10)
[Clang 13.0.0 (clang-1300.0.29.30)] on darwin
Type "help", "copyright", "credits" or "license" for more information.
>>> print("Hello Work!")
Hello Work!
>>>
```

Figure: First program in Python

Plan of the course

- Introduction to Python
- Basic Syntax, Variables and Data Types
- Functions
- Modules
- Files I/O
- Exception Handling
- OOP

Basic Syntax, Variables, and Data Types

Indentation in Python

- Python uses indentation to define blocks of code. This is different from many other programming languages, which use curly braces to define blocks such as C, C++ or Java. Here's an example:

```
if x > 0:  
    print("x is positive")  
else:  
    print("x is not positive")
```

- The indentation tells Python which lines of code belong to each block.
- Use the **tab** key in order to indent your code.

Line Endings in Python

- In Python, a line of code ends with a newline character. You can also use a backslash (\) to indicate that a statement continues on the next line. Here's an example:

```
x = 5 + \  
10  
print(x) # Output: 15
```

- In this example, the backslash tells Python that the + operator is part of the previous line, and the value of x is 15.

Comments in Python

- You can add comments to your Python code to explain what the code does. Comments start with a hash (#) character and continue until the end of the line. Here's an example:

```
# This is a comment  
print("Hello, world!")
```

- In this example, the first line is a comment, and Python ignores it when running the code. The second line prints the message "Hello, world!" to the console. Comments can be used to make your code more readable and easier to understand.

Variables in Python

- In Python, a variable is a name that refers to a value. You can assign a value to a variable using the assignment operator (=). Here's an example:

```
x = 10  
print(x)
```

- This code assigns the value 10 to the variable `x` and then prints the value of `x` to the console.
- Variables can hold different types of values, such as integers, floats, strings, and booleans. You can even assign a variable to another variable.

Variable Names in Python

- In Python, variable names can contain letters, numbers, and underscores. They must start with a letter or underscore, and they are case-sensitive. Here are some examples of valid variable names:

```
age = 30  
name = "John"  
my_score = 9.5  
is_student = True
```

- It's important to choose meaningful and descriptive names for your variables, so that your code is easier to read and understand.

Variable Assignment in Python

- In Python, you can assign a value to a variable using the assignment operator (=). You can also assign the same value to multiple variables at once. Here's an example:

```
x = y = z = 0  
print(x, y, z)
```

- This code assigns the value 0 to the variables `x`, `y`, and `z` all at once, and then prints their values to the console.
- You can also assign different values to multiple variables in a single line of code, separated by commas.

Data Types in Python: Integers

- Python supports several data types, including integers, floats, strings, booleans, lists, tuples, sets, and dictionaries. Let's take a closer look at each one.
- **Integers** are whole numbers, such as -3, -2, -1, 0, 1, 2, 3 etc. You can perform basic arithmetic operations on integers, such as addition, subtraction, multiplication, and division.

```
x = 3
```

```
y = 2
```

```
print(x + y) # Output: 5
```

Data Types in Python: Floats and Strings

- **Floats** are decimal numbers, such as 3.14, 2.0, and -1.5. You can also perform basic arithmetic operations on floats.

```
x = 3.14  
y = 2.0  
print(x * y) # Output: 6.28
```

- **Strings** are sequences of characters, such as "hello", "world", and "Python". You can concatenate strings using the + operator.

```
x = "hello"  
y = "world"  
print(x + " " + y) # Output: "hello world"
```

Data Types in Python: Booleans

- **Booleans** are either True or False. They are often used in conditional statements and loops.

```
x = 10  
y = 5  
print(x > y) # Output: True
```

- **Lists, tuples, sets, and dictionaries** are collections of values. They have different properties and methods for manipulating and accessing their elements.

Lists in Python

- A list is a collection of values that are ordered and mutable. Lists are created using square brackets [] and each value is separated by a comma.

```
fruits = ["apple", "banana", "orange"]  
print(fruits[0]) # Output: "apple"  
fruits.append("grape")  
print(fruits) # Output: ["apple", "banana", "orange", "grape"]
```

- You can access and modify individual elements of a list using their index. You can also add or remove elements using built-in methods like `append()`, `insert()`, `remove()`, and `pop()`.

Tuples in Python

- A tuple is a collection of values that are ordered and immutable. Tuples are created using parentheses () and each value is separated by a comma.

```
colors = ("red", "green", "blue")  
print(colors[1]) # Output: "green"
```

- You can access individual elements of a tuple using their index, but you cannot modify the elements themselves. Tuples are useful for representing fixed collections of values.

Sets in Python

- A set is a collection of values that are unordered and unique. Sets are created using curly braces or the set() function and each value is separated by a comma.

```
fruits = { "apple", "banana", "orange" }  
print("apple" in fruits) # Output: True  
fruits.add("grape")  
print(fruits) # Output: "apple", "banana", "orange", "grape"
```

- You can check if a value is in a set using the in operator. You can also add or remove elements using built-in methods like add(), remove(), and discard().

Dictionaries in Python

- A dictionary is a collection of key-value pairs that are unordered and mutable.

Dictionaries are created using curly braces and each key-value pair is separated by a colon .:

```
person = { "name": "John", "age": 30, "city": "New York" }  
print(person["name"]) # Output: "John" person["age"] = 31  
print(person)  
# Output: { "name": "John", "age": 31, "city": "New York" }
```

- You can access and modify values in a dictionary using their keys. You can also add or remove key-value pairs using built-in methods like `update()`, `pop()`, and `copy()`.

Alternate and Repeating Conditional Structures and Loops

- In algorithms and programming, we call a **conditional structure** the set of instructions that test whether a condition is true or not. There are three of them:
 - The conditional structure **if**:

```
if condition:  
    my_instructions
```

Alternate and Repeating Conditional Structures and Loops

■ Continuation:

- The Conditional Structure **if ...else** :

```
if condition:  
    my_instructions  
else:  
    my_other_instructions
```

Alternate and Repeating Conditional Structures and Loops

■ Continuation:

- The conditional structure `if ...elif ...else :`

```
if condition_1:
    my_instructions_1
elif condition_2:
    my_instructions_2
else:
    my_other_instructions
```

Alternate and Repeating Conditional Structures and Loops

- Furthermore, an **iterative conditional structure** allows the same series of instructions to be executed several times (iterations). The **while** instruction executes the instruction blocks as long as the while condition is true. The same principle for the **for** loop (for), the two structures are detailed below:
 - The iterative Conditional Structure **while**:

```
while condition:  
    my_instructions
```

Alternate and Repeating Conditional Structures and Loops

■ Continuation:

- The iterative conditional structure **for**:

```
for i in range(start, stop, step):  
    my_instructions
```

- **Remark:** The major difference between for loop and the while loop is that for loop is used when the number of iterations is known, whereas execution is done in the while loop until the statement in the program is proved wrong.

Alternate and Repeating Conditional Structures and Loops

- The iterative conditional structure **for**:

```
for variable in iterable:  
    my_instructions
```

Functions in Python

- One may want to define a function in order to use it in a program, the general syntax of declaring and defining a function is as follow:

```
def theFunctionName(args if any):  
    # function implementation  
    # function implementation  
    # function implementation
```

- A function will always be defined with the keyword **def**.
- Please note the importance of indentation in the function implementation.

Functions in Python: example 1

Defining a function without parameters and without any returns:

```
# Defining the utility function printLine
def printLine():
    print("-----")

# Testing our function
printLine()
```

Functions in Python: example 2

Defining a function that takes a number as a parameter and returns its square

```
# Defining our square function
def Square(n):
    return n**2

# Testing our function
Square(4)
```

Note the usage of the ****** operator in order to calculate the power of a number.

Notion of recursivity: recursive functions

Definitions:

- An algorithm is called **recursive** if it is defined by it-self.
- In the same manner, a function is called **recursive** if it references itself.

Functions in Python: example 3

Defining a recursive function with a parameter and no returns (the return is returning void):

```
# Defining our recursive function Count
```

```
def Count(n):
```

```
    print(n)
```

```
    if n == 0 :
```

```
        print("Done.")
```

```
        return
```

```
    Count(n-1)
```

```
# Testing our function
```

```
Count(10)
```

Lambda Functions

- Python Lambda functions are:
 - Small
 - Anonymous
 - Subject to a more restrictive syntax
 - Concise
 - Taking any number of arguments, but can only have one expression.
- We define a Lambda function with the keyword **lambda**.
- The general syntax of a lambda function is the following:

```
lambda args : implementation
```

Lambda Functions: examples

Example 1: lambda function with 1 parameter

```
f = lambda x : 2 * x
```

```
print( f(50) )
```

#Output: 100.

Example 2: lambda function with 2 parameters

```
fun = lambda a, b : a ** b
```

```
print(fun(7, 2))
```

#Output: 49.

Usage of Lambda Functions

- The utility of a Lambda function is when you use it as an anonymous function inside another function.
- A complete example is shown below:

```
def multiplier(n):  
    return lambda x : x * n  
Doubler = multiplier(2)  
Tripler = multiplier(3)  
print(Doubler(33)) # Outputs: 66  
print(Tripler(33)) # Outputs: 99
```

Variable number of parameters in a function

- Python allows you to create functions with a variable number of parameters (e.g. `print()` is a function that can receive an arbitrary number of parameters). The general syntax of such functions is:

```
def functionName(*args):  
    # instructions
```

```
# Example:  
def foo(*args):  
    for arg in args:  
        print(arg)  
foo("Hello", 1, 2, 3, "World")
```

Functions with key/value parameters

- Parameters can also be managed as keys/values to populate a dictionary:

```
def functionName(**kwargs) :  
    # instructions
```

```
# Example:  
def printDict(**kwargs):  
    for (k, v) in kwargs.items() :  
        print(k, v)  
  
printDict(Day_1="Monday", Day_2="Tuesday"))
```

Generators

- A generator is implemented with the **yield** keyword, it permits to creates a flux of data. A kind of data reservoir; which can be called up piecewise by **next()**.

```
def Generator():  
    for i in range(10, 0, -1):  
        yield i  
gen = Generator()  
print(next(gen)) # Outputs : 10  
print(next(gen)) # Outputs : 9
```

Modules and Importing

- **What are modules in Python?** In Python, a module is a file containing Python code that can be imported into other Python scripts. Modules are used to organize code into separate files and provide a way to reuse code across different programs. To create a module, you simply write Python code in a file with a .py extension. You can then import the module into another Python script using the **import** statement.
- **How do you import modules in Python?**
To import a module in Python, you use the **import** statement followed by the name of the module. For example, if you have a module named "my_module.py", you can import it into another Python script with the following statement:

```
import my_module
```

Modules and Importing

- Once you have imported the module, you can use its functions and variables in your code. To call a function from the module, you use the dot notation, like this:

```
my_module.my_function()
```

- You can also use the **from** keyword to import specific functions or variables from a module, like this:

```
from my_module import my_function, my_variable
```

- This allows you to use the imported functions and variables without having to prefix them with the module name.

Best practices for modules in Python

- When importing modules in Python, there are some best practices you should follow to ensure that your code is clean, readable, and maintainable. Here are a few tips:
 - Use absolute imports to specify the full path to the module you want to import. This makes it clear which module you are importing and helps avoid naming conflicts.
 - Avoid using wildcard imports (e.g. `from my_module import *`) as they can make it difficult to understand where functions and variables are coming from.
 - Use aliases to shorten module names and make them easier to use. For example, you could import the numpy module as `np` like this: `import numpy as np`.

Best practices for modules in Python

■ Continuation:

- Group related imports together at the top of your script to make it clear which modules your code depends on.
- Avoid circular imports, where two modules depend on each other. This can create confusing dependencies and make your code harder to understand.

- By following these best practices, you can ensure that your Python code is well-organized, easy to read, and maintainable over time.

Files I/O in Python

Files I/O in Python

- Input and output operations on files are an essential part of many programs.
- In Python, you can use the built-in functions `open()` and `close()` to work with files.
- To read data from a file, you can use the `read()` method.
- To write data to a file, you can use the `write()` method.

Files I/O in Python Reading Data Example

- Here's an example of how to read data from a file:

```
# Open the file in read mode
file = open("myfile.txt", "r")
# Read the contents of the file
data = file.read()
# Close the file
file.close()
# Print the data
print(data)
```

Files I/O in Python Writing Data Example

- And here's an example of how to write data to a file:

```
# Open the file in write mode
file = open("myfile.txt", "w")
# Write some data to the file
file.write("Hello, world!")
# Close the file
file.close()
```

Working with files in Python: specifications 1

By default, `open()` opens the file in text mode, which means that it reads and writes strings. If you want to work with binary data, you can use the `open()` function with the "b" mode modifier (`wb` or `rb`). Remember to always close your files when you're done working with them, as this releases any system resources associated with the file and helps prevent data corruption.

Working with files in Python: specifications 2

Working with File Paths in Python

- When working with files in Python, it's important to specify the correct file path.
- The file path is the location of the file on your computer.
- In Windows, file paths use the backslash (\) character to separate directories.
- In Linux and macOS, file paths use the forward slash (/) character.

Working with files in Python: specifications 3

- You can use the `os` module in Python to work with file paths.
- The `os.path.join()` method is a platform-independent way of joining path components.
- Here's an example of how to use `os.path.join()` to construct a file path:

Working with files in Python: specifications 4

```
import os
# Join path components to construct a file path
filepath = os.path.join("mydir", "myfile.txt")
# Open the file
file = open(filepath, "r")
# Read the contents of the file
data = file.read()
# Close the file
file.close()
# Print the data
print(data)
```

Working with files in Python: specifications 5

- In this example, `os.path.join()` joins the directory name "mydir" and the file name "myfile.txt" to construct the file path "mydir/myfile.txt".
- This is done in a platform-independent way, so the code will work on both Windows and Unix-based systems.
- By using the `os` module and the `open()` function, you can work with files and file paths in a way that is both easy and reliable.

Appending Data to a File in Python

- In addition to reading and writing data to a file, you can also append data to an existing file in Python. This allows you to add new data to the end of a file without overwriting its existing contents.
- To append data to a file, you can use the a mode modifier when opening the file. Here's an example:

```
# Open the file in append mode
file = open("myfile.txt", "a")
# Write some data to the file
file.write("Hello, again!")
# Close the file
file.close()
```

Appending Data to a File in Python Continuity

- In this example, the file "myfile.txt" is opened in append mode using the a mode modifier.
- The write() method is used to add the string "Hello, again!" to the end of the file, without overwriting its existing contents.
- Remember to always close your files when you're done working with them,
as this releases any system resources associated with the file and helps prevent data corruption.

Exception Handling

Exception Handling in Python

- In programming, errors and exceptions are common occurrences that can cause programs to crash or behave unexpectedly. In order to handle these errors, Python provides a mechanism called "**exception handling**."
- **Exception handling** allows you to catch and handle errors in your code so that your program can continue running gracefully even if errors occur. You can use the **try**, **except**, and **finally** keywords to handle exceptions in your code.

Exception Handling

Exception Handling in Python

- The **try block** contains the code that might raise an exception, and the **except block** contains the code that is executed if an exception is raised.
- You can catch specific types of exceptions by specifying the exception class after the **except** keyword.
- The **finally block** contains code that is always executed, regardless of whether an exception is raised or not. This block is typically used to clean up resources that were used in the try block.

Exception Handling

- Here's the basic syntax for exception handling in Python:

```
try:  
    # Code that might raise an exception  
except ExceptionType:  
    # Code to handle the actual exception  
finally:  
    # Code that is always executed
```

- Exception handling make your programs more robust and less likely to crash or behave unpredictably when errors occur.

Exception Handling: Example 1

Example 1: Let's say you want to open a file in Python and perform some operations on it. However, there's a chance that the file might not exist or that you don't have permission to access it. In this case, you can use exception handling to catch the error and handle it gracefully.

Exception Handling: Example 1 Continuity

```
try:
    f = open("myfile.txt", "r")
    # Performing some operations on our file myfile.txt
    f.close()
except FileNotFoundError:
    print("File not found.")
except PermissionError:
    print("You don't have permission to access this file.")
except Exception as e:
    print("An error occurred:", e)
```

Exception Handling: Example 2

Example 2: You might encounter an error if you try to divide a number by zero. To avoid this error, you can use exception handling.

```
try:  
    result = 10 / 0  
except ZeroDivisionError:  
    print("You cannot divide by zero.")  
except Exception as e:  
    print("An error occurred:", e)
```

Exception Handling: Example 3

Example 3: Let's say you have a list of numbers and you want to iterate over them and perform some calculations. However, some of the numbers might not be valid, so you need to use exception handling to catch the errors.

Exception Handling: Example 3 Continuity

```
my_list = [ 1, 2, 3, "four", 5 ]
for num in my_list:
    try:
        result = 10 / num
        print(result)
    except TypeError:
        print("Invalid data type:", num)
    except ZeroDivisionError:
        print("You cannot divide by zero.")
    except Exception as e:
        print("An error occurred:", e)
```

`/* Fundamental Principles of Object-Oriented Programming (OOP) */`

Fundamental Principles of OOP

Definition: Object-Oriented Programming (OOP) is one of the fundamental principles in computer programming, with origins dating back to the 1970s with the Simula and Smalltalk languages, but the principle quickly took off with the creation of the C++ language, which is an extension of the C language, with the aim of making software more robust.

Fundamental Principles of OOP (continued)

A useful mnemonic device for the **six fundamental principles** of Object-Oriented Programming is "**ACOPIE**".

- *Abstraction*
- *Class*
- *Object*
- *Polymorphism*
- *Inheritance*
- *Encapsulation*

Object

- In computer science, an object is a self-contained symbolic container that holds information and functions/methods related to a subject, manipulated in a program. The subject is often something tangible belonging to the real world.

Class

- The class is a special data structure in object-oriented programming languages.
- It describes the internal structure of data and defines the methods that will apply to objects of the same family (the same class) or type.
- It provides methods for creating objects whose representation will therefore be that given by the generating class. The objects are then said to be instances of the class. This is why an object's attributes are also called instance variables and messages are called instance operations or instance methods.

Encapsulation

- Encapsulation is the act of grouping data and methods that manipulate them into a single entity called a *capsule*.
- It allows for organized code, restricting access to certain portions from outside the capsule, and having robust code.

Abstraction

- Abstraction is one of the key concepts in object-oriented programming languages. Its main purpose is to manage complexity by hiding unnecessary details from the user.
- Abstraction is the process of representing a real-life object as a computer model.
- This essentially involves extracting relevant variables attached to the objects we want to manipulate and placing them into a suitable computer model.

Inheritance

- It is a mechanism for transmitting all the methods of a so-called "mother" class to another called "daughter" and so on.

Polymorphism

- The name of polymorphism comes from Greek and means "many forms." This characteristic is one of the essential concepts of object-oriented programming. While inheritance concerns classes (and their hierarchy), polymorphism is related to object methods.

Creating a Class

```
class Car:
    def __init__(self, make, model, year):
        self.make = make
        self.model = model
        self.year = year
    def get_make(self):
        return self.make
    def get_model(self):
        return self.model
    def get_year(self):
        return self.year
```

Instantiating Objects

```
car1 = Car("Toyota", "Camry", 2020)
car2 = Car("Honda", "Accord", 2021)
print(car1.get_make())
print(car2.get_make())
print(car1.get_model())
print(car2.get_model())
print(car1.get_year())
print(car2.get_year())
```

Inheritance and Polymorphism

```
class Animal:
    def __init__(self, name):
        self.name = name
    def make_sound(self):
        pass
    def animal_sounds(animal):
        animal.make_sound()
class Dog(Animal):
    def make_sound(self):
        print("Woof!")
class Cat(Animal):
    def make_sound(self):
        print("Meow!")
```

Inheritance and Polymorphism

```
dog = Dog("Rufus")  
cat = Cat("Whiskers")  
dog.animal_sounds()  
cat.animal_sounds()
```
